Principal component regression (PCR)

Trevor Hastie and Robert Tibshirani

Here, I am adapting part of the lab associated with Chapter 6 of the textbook.

Data Prep

We wish to predict a baseball player's Salary on the basis of various statistics associated with performance in the previous year.

First of all, we note that the Salary variable is missing for some of the players. The is.na() function can be used to identify the missing observations. It returns a vector of the same length as the input vector, with a TRUE for any elements that are missing, and a FALSE for non-missing elements. The sum() function can then be used to count all of the missing elements.

```
library(ISLR2)
data(Hitters)
names (Hitters)
    [1] "AtBat"
                     "Hits"
                                  "HmRun"
                                               "Runs"
                                                            "RBI"
                                                                        "Walks"
##
                     "CAtBat"
                                                                        "CRBI"
    [7] "Years"
                                  "CHits"
                                               "CHmRun"
                                                            "CRuns"
## [13] "CWalks"
                     "League"
                                               "PutOuts"
                                                                        "Errors"
                                  "Division"
                                                            "Assists"
## [19] "Salary"
                     "NewLeague"
#View(Hitters)
dim(Hitters)
## [1] 322 20
sum(is.na(Hitters$Salary))
```

[1] 59

Hence we see that Salary is missing for 59 players. The na.omit() function removes all of the rows that have missing values in any variable.

```
Hitters <- na.omit(Hitters)
dim(Hitters)

## [1] 263 20
sum(is.na(Hitters))

## [1] 0

All is well now, so we attach the data for ease of use.
attach(Hitters)</pre>
```

Principal Components Regression

53.01

53.85

Salary

Principal components regression (PCR) can be performed using the pcr() function, which is part of the pls library. We now apply PCR to the Hitters data, in order to predict Salary.

```
#install.packages("pls")
library(pls)
##
## Attaching package: 'pls'
## The following object is masked from 'package:stats':
##
##
       loadings
set.seed(1)
pcr.fit <- pcr(Salary ~ ., data = Hitters, scale = TRUE,</pre>
    validation = "CV")
```

The syntax for the pcr() function is similar to that for lm(), with a few additional options. Setting scale = TRUE has the effect of standardizing each predictor, prior to generating the principal components, so that the scale on which each variable is measured will not have an effect. Setting validation = "CV" causes pcr() to compute the ten-fold cross-validation error for each possible value of M, the number of principal components used. The resulting fit can be examined using summary().

```
summary(pcr.fit)
## Data:

                                     54.61
```

The CV score is provided for each possible number of components, ranging from M=0 onwards. Note that pcr() reports the root mean squared error; in order to obtain the usual MSE, we must square this quantity.

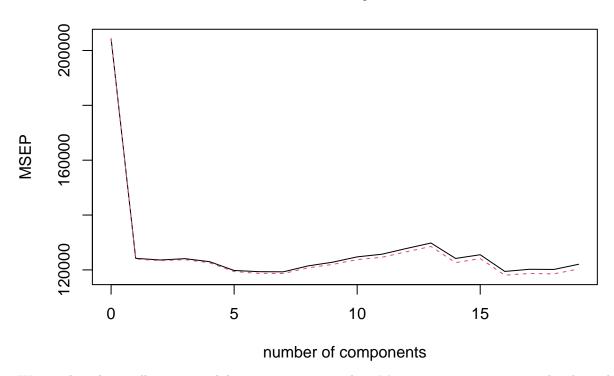

54.61

For instance, a root mean squared error of 352.8 corresponds to an MSE of $352.8^2 = 124,468$.

One can also plot the cross-validation scores using the validationplot() function. Using val.type = "MSEP" will cause the cross-validation MSE to be plotted.

```
validationplot(pcr.fit, val.type = "MSEP")
```

Salary

We see that the smallest cross-validation error occurs when M=18 components are used. This is barely fewer than M=19, which amounts to simply performing least squares, because when all of the components are used in PCR no dimension reduction occurs. However, from the plot we also see that the cross-validation error is roughly the same when only one component is included in the model. This suggests that a model that uses just a small number of components might suffice.

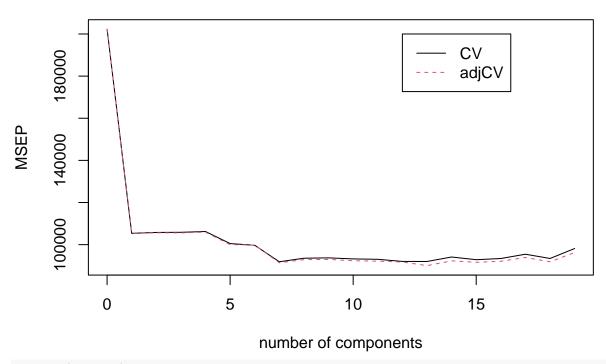

The summary() function also provides the percentage of variance explained in the predictors and in the response using different numbers of components. Briefly, we can think of this as the amount of information about the predictors or the response that is captured using M principal components. For example, setting M=1 only captures 38.31% of all the variance, or information, in the predictors. In contrast, using M=5 increases the value to 84.29%. If we were to use all M=p=19 components, this would increase to 100%.

We now perform PCR on the training data and evaluate its test set performance.

```
set.seed(1)
#splitting the data set
train <- sample(c(TRUE, FALSE), nrow(Hitters),
    replace = TRUE)
test <- (!train)

pcr.fit <- pcr(Salary ~ ., data = Hitters, subset = train,
    scale = TRUE, validation = "CV")
validationplot(pcr.fit, val.type = "MSEP", legendpos = t(c(12,200000)))</pre>
```

Salary

                                            100.00
## Salary
               64.6
                         65.43
                                   66.49
                                              66.58
```

Now we find that the lowest cross-validation error occurs when M=5 components are used. We compute the test MSE as follows.

```
x <- model.matrix(Salary ~ ., Hitters)[, -1]</pre>
y <- Hitters$Salary
y.test <- y[test]</pre>
pcr.pred <- predict(pcr.fit, x[test, ], ncomp = 5)</pre>
mean((pcr.pred - y.test)^2)
## [1] 136435.5
Finally, we fit PCR on the full data set, using M = 5, the number of components identified by cross-validation.
pcr.fit <- pcr(y ~ x, scale = TRUE, ncomp = 5)</pre>
summary(pcr.fit)
